### Tables

1. Life table for the total population: United States, 1959-61-----	8
2. Life table for total males: United States, 1959-61-----	10
3. Life table for total females: United States, 1959-61-----	12
4. Life table for total whites: United States, 1959-61-----	14
5. Life table for white males: United States, 1959-61-----	16
6. Life table for white females: United States, 1959-61-----	18
7. Life table for total nonwhites: United States, 1959-61-----	20
8. Life table for nonwhite males: United States, 1959-61-----	22
9. Life table for nonwhite females: United States, 1959-61-----	24
10. Proportion of persons dying during year at specified ages, who were alive at beginning of year of age, by color and sex: Death-registration States, at 10-year intervals, 1900-1902 to 1959-61-----	26
11. Number surviving to specified ages out of 100,000 born alive, by color and sex: Death-registration States, at 10-year intervals, 1900-1902 to 1959-61-----	28
12. Average remaining lifetime in years at specified ages, by color and sex: Death-registration States, at 10-year intervals, 1900-1902 to 1959-61 -----	30

# UNITED STATES LIFE TABLES: 1959-61

## Generation and Current Life Tables

The mortality rates for a specific period may be summarized by the life table method to obtain measures of comparative longevity. There are two types of life tables—the generation or cohort life table and the current life table. The generation life table provides a "longitudinal" perspective in that it follows the mortality experience of an actual cohort—for example, all persons born in the year 1900—from the moment of birth through consecutive ages in successive calendar years. Based on age-specific mortality rates observed during consecutive calendar years, the generation life table reflects the mortality experience of a cohort from birth until no lives remain in the group.

The better-known current life table may, by contrast, be characterized as "cross-sectional." Unlike the generation life table, the current life table does not represent the mortality experience of an actual cohort. Rather, the current life table considers a hypothetical cohort and assumes that it is subject throughout its existence to the age-specific mortality rates observed for an actual population during a particular period of relatively short duration (often 1 to 3 years).

## Decennial Life Tables, 1959-61

The life tables contained in this report are current life tables based on age-specific mortality rates for the period 1959-61. These mortality rates have been calculated from data of the 1960 census of population and deaths occurring in the United States in the 3-year period 1959-61. In deriving life table values at ages under 2, where census data are significantly affected by under-enumeration, use has been made also of reported births for each of the years 1957 to 1961. Tables

are given for whites and nonwhites, separately by sex and for both sexes combined, and also for the total population and for total males and total females (tables 1-9).

These tables are the most recent in a series of life tables that have been prepared at 10-year intervals for the death-registration States, which began with those for 1900-1902. Each of the tables in the series is based on a census of population and deaths in a 3-year period containing the census year. These decennial life tables differ in two main respects from the life tables prepared annually and published in the annual volumes *Vital Statistics of the United States*: (1) the annual tables are based on deaths of a single year and on postcensal population estimates, rather than directly on the data of a decennial census, and (2) the annual tables are calculated by abbreviated methods.

The life tables in this report are the result of a joint effort by the National Center for Health Statistics, Public Health Service, and the Division of the Actuary, Social Security Administration. The Division of the Actuary played the primary role in developing the methodology used, while the computer programming and calculation of the life table values was primarily the responsibility of the National Center for Health Statistics.

## Accuracy of Life Table Values

The accuracy of the life table values probably compares favorably with the accuracy of the statistics on which they are based. However, it is well known that the underlying data are subject to serious errors, the magnitude of which is usually difficult to estimate precisely. The only type of error that was deemed sufficiently serious to warrant adjustment prior to the calculation of the life tables concerned apparent inaccuracy in

statements of age by nonwhites in the neighborhood of age 60. In order to avoid anomalous life table values, the nonwhite population at ages 55-64 years was reallocated between the 5-year groups 55-59 and 60-64.

Proportions dying ( $q_x$ ) at ages 95 and over, where the available data are especially scanty and unreliable, are not based on actual statistics at these ages. In part, this is also true of ages 85-94. Thus, the life table functions at ages 85 and above may not represent actual conditions, and, in fact, the proportions dying at ages 95 and over have the same numerical values in all nine tables.

A later publication will contain a complete description of the adjustments made in the basic data and of the methods and formulas by which the life tables were prepared.

### Measures of Comparative Longevity

The life table provides a convenient tool for comparing the longevity of different populations or of different subdivisions of a population. The customary measure of longevity is the average duration of life, also called the expectation of life at birth. This is the average number of years lived by the members of the life table cohort. Based on the mortality experience of 1959-61, the expectation of life at birth is 67.55 years for white males, 74.19 for white females, 61.48 for nonwhite males, and 66.47 for nonwhite females. These values reflect the higher mortality of males over females and of nonwhites over whites. Expectation of life at birth for white females is 6.64 years longer than for white males, and the corresponding excess for nonwhite females over nonwhite males is 4.99 years. However, because of the substantially higher mortality of nonwhites over whites, the expectation of life at birth for white males exceeds that for nonwhite females by 1.08 years.

Expectation of life at birth ( $\bar{e}_0$ ) is strongly affected by the relatively large number of deaths occurring during the first year of life. In comparing the longevity of different populations, it may be desired to consider also expectation of life at age one ( $\bar{e}_1$ ), since this measure is not affected by the infant mortality rate. Indeed, as shown in tables 1-9,  $\bar{e}_1$  is greater than  $\bar{e}_0$  in all population groups; those persons in the

hypothetical cohort who survive the hazards of infancy exhibit an increase in the average number of years of life remaining over the number expected when they were 1 year younger. The 1959-61 values of  $\bar{e}_1$  are 68.34 years for white males, 74.68 for white females, 63.50 for nonwhite males, and 68.10 for nonwhite females. The increase in expectation of life at age 1 over age 0 is substantial for nonwhite males and females (2.02 and 1.63 years, respectively) but much less for white males and females (0.79 and 0.49 years, respectively); this reflects the higher infant mortality of the nonwhite population.

It may be of interest for certain purposes to examine average remaining lifetime at other ages. For example, ages 21, 62, and 65 may be regarded as representing, respectively, the attainment of adulthood, the minimum retirement age prescribed by the Social Security Act, and the normal retirement age. The 1959-61 values of expectation of life at age 21 are 49.33 years for white males, 55.32 for white females, 44.89 for nonwhite males, and 49.12 for nonwhite females. Corresponding values for age 62 are 14.75, 18.13, 14.26, and 16.72 years; and for age 65 they are 12.97, 15.88, 12.84, and 15.12 years.

The concept of "expectation of life" is misleading if it is taken to imply the notion of forecasting. It is important to understand that expectation of life values forecast average remaining lifetime only for the hypothetical cohort of the life table. Comparable forecasts for any actual population would have to take into consideration future mortality trends as well as current mortality rates.

Another possible yardstick for comparing the longevity of different populations is the median length of life, or "probable lifetime," which is the age at which exactly half the members of the original life table cohort have died. When the cohort starts with 100,000 births, this would be the age at which there are just 50,000 survivors. Easily calculated from the  $I_x$  values in the life tables, the median length of life at birth, based on the mortality rates of 1959-61, is 71.45 years for white males, 78.46 for white females, 65.62 for nonwhite males, and 70.61 for nonwhite females. In calculating the median length of life it is assumed that deaths are evenly distributed within the age interval containing the median age.

A comparison of the "probable lifetime" with the expectation of life at birth shows that the former exceeds the latter for each population group. Thus, the median length of life at birth for 1959-61 is 3.90 years longer than the expectation of life at birth for white males; for white females, 4.27 years; for nonwhite males, 4.14; and for nonwhite females, 4.14. These differences are due to the asymmetrical or "skewed" character of the statistical distribution of deaths in the life table cohort; the relatively large number of deaths in the first year of life plays a major role in producing this asymmetry.

Still another measure of comparative longevity is the number (or percentage) of persons in the original cohort surviving to a specified age. Such data are supplied directly by the  $I_x$  column in the life tables. Thus, on the basis of 1959-61 mortality, the percentage of white males surviving to age 1 is 97.4; of white females, 98.0; of nonwhite males, 95.3; and of nonwhite females, 96.2. At age 21 the corresponding percentages are 95.8, 97.1, 92.9, and 94.6; and at age 65 they are 65.8, 80.7, 51.4, and 60.8.

### Secular Trend of Life Table Values, 1900-1961

Selected life table values for seven decennial life tables covering the period 1900-1961 are given in tables 10-12, by color and sex. In interpreting these tables it must be remembered that values for the different 3-year periods are not strictly comparable. The area covered at each period was limited to the death-registration States. In 1929-31 for the first time these included the 48 contiguous States and the District of Columbia; Alaska and Hawaii are included for the first time in 1959-61. Moreover, the values for periods before 1949-51 do not cover all nonwhites, but are limited to Negroes only.

### EXPLANATION OF THE COLUMNS OF THE LIFE TABLE

(Figures used for illustration are from table 5)

**Column 1—Age interval ( $x$  to  $x + t$ ).**—The age interval shown in column 1 is the interval between the two exact ages indicated. For instance, "3-28 days" means the 25-day interval between the exact ages of 3 days and 28 days, and "43-44 years" means the interval of 1 year between the 43d and 44th birthdays. In the life tables in

It should be remembered, also, that there has been progressive improvement in the completeness of death reporting during this period.

It seems unlikely that variations in the coverage of the life tables from period to period would seriously bias the major trends in the values for 1900-1961. However, it is believed that the fluctuations appearing at certain ages in the values for Negroes during the first 30 years of the century may be attributable, in part, to the expanding character of the death-registration area, and, in part, to progressive improvement in the completeness of death reporting.

Since the turn of the century there has been a spectacular improvement in expectation of life for all subdivisions of the population by color and sex. This increase in longevity has been appreciably greater for females than for males, and for nonwhites than for whites. The relative improvement in longevity of females is particularly striking because it has increased the disparity in expectation of life between the sexes. The average duration of life (table 12) has increased by 19.32 years for white males, 23.11 years for white females, 28.94 years for nonwhite males, and 31.43 years for nonwhite females. The proportion dying during the first year of life (table 10) has decreased by 80.6 percent for white males, 82.2 percent for white females, 81.4 percent for nonwhite males, and 82.2 percent for nonwhite females. The number attaining age 65 in a life table cohort of 100,000 live births (table 11) has increased by 26,589 for white males, by 36,933 for white females, by 32,377 for nonwhite males, and by 38,830 for nonwhite females. For all four subdivisions of the population, the improvement in average remaining lifetime becomes progressively less at older ages, but recent values even at relatively old ages are substantially higher than in 1900-1902.

this report the age interval is always 1 year except in the case of subdivisions of the first year of life.

**Column 2—Proportion dying ( $tq_x$ ).**—This column shows the proportion of the members of the life table cohort alive at the beginning of the indicated age interval who will die before reaching

the end of that age interval (in most instances, the next birthday). For example, for white males (table 5) in the age interval 3-28 days, the proportion dying is 0.00392—out of every 1,000 white male babies surviving 3 days after birth, 3.92 will die before reaching the age of 28 days. Similarly, for white males in the age interval 43-44 years, the proportion dying is 0.00454—out of every 1,000 white males reaching their 43d birthday, 4.54 would die before reaching their 44th birthday, on the basis of the mortality rates of 1959-61. When the age interval is 1 year, the symbol  $q_x$  (instead of  ${}_1q_x$ ) is generally used for the proportion dying.

*Column 3—Number surviving ( $I_x$ ).*—This column shows the number of persons, starting with a cohort of 100,000 live births, who survive to the exact age marking the beginning of the indicated age interval. Thus, out of 100,000 white male babies born alive, 98,418 will survive 3 days, 97,408 will complete the first year of life and enter the second, 95,755 will reach age 21, and 40,207 will live to age 75.

*Column 4—Number dying ( ${}_1d_x$ ).*—This column shows the number dying in each successive age interval out of 100,000 live births. Thus, out of 100,000 white males born alive, 386 die between the ages of 3 and 28 days, 2,592 die in the entire first year of life, and 415 in the year between their 43d and 44th birthdays. Evidently, each figure in column 4 is the difference between two successive figures in column 3. When the age interval is 1 year, the symbol  $d_x$  (instead of  ${}_1d_x$ ) is generally used for the number dying.

*Columns 5 and 6—Stationary population ( ${}_tL_x$  and  $T_x$ ).*—Suppose that a group of 100,000 persons like that assumed in columns 3 and 4 is born every year and that the proportions dying in each such group in each age interval throughout the lives of the members are exactly those shown in column 2. If there were no migration and if the births were evenly distributed over the calendar year, the survivors of these births would constitute what is called a stationary population—stationary because in such a population the number of persons living in any given age interval would never change. When an individual left an age interval, whether by death or by growing older and entering the next higher age interval, his place would immediately be taken by someone entering

from the next lower age interval. Thus, a census taken at any time in such a stationary community would always show the same total population and the same numerical distribution of that population among the various age intervals. In such a stationary population supported by 100,000 annual births, column 3 shows the number of persons who, each year, reach the exact age that marks the beginning of the age interval indicated in column 1, and column 4 shows the number of persons who die each year in the indicated age interval.

Column 5,  ${}_tL_x$ , shows the number of persons in the stationary population in the indicated age interval. For example, the figure shown for white males in the age interval 3-28 days is 6,722. This means that in a stationary population of white males supported by 100,000 annual births and with proportions dying in each age interval always in accordance with column 2, a census taken on any date would show 6,722 persons between the exact ages of 3 and 28 days. Similarly, the figure for white males in the year of life 43-44 is 91,198. Thus, the stationary population described would always contain 91,198 persons between their 43d and 44th birthdays. When the age interval is 1 year, the symbol  $L_x$  is generally used instead of  ${}_tL_x$ .

Column 6,  $T_x$ , shows the total number of persons in the stationary population (column 5) in the indicated age interval and all subsequent age intervals. For example, in the stationary population of white males described in the preceding paragraph, column 6 shows that there would be at any given moment a total of 6,754,034 persons who have survived at least 3 days following birth, and a total of 2,657,169 persons who have attained age 43. The population at all ages 0 and above (in other words, the total white male population of the stationary community) would be 6,754,846.

*Column 7—Average remaining lifetime ( $\bar{e}_x$ ).*—The average remaining lifetime (also called expectation of life) at any given age is the average number of years remaining to be lived by those surviving to that age, on the basis of a given set of age-specific rates of dying. In order to relate these figures to the preceding columns of the life table it is necessary to observe that the figures in column 5 of the life tables can also be interpreted

in terms of a single life table cohort without introducing the concept of the stationary population. From this point of view, each figure in column 5 represents the total time (in years) lived between two indicated exact ages by all those reaching the earlier age among the survivors of a cohort of 100,000 live births. Thus, the figure 6,722 for white males in the age interval 3-28 days is the total number of years of life lived between the exact ages of 3 and 28 days by the 98,418 (column 3) who reached the age of exactly 3 days out of 100,000 white males born alive. The corresponding figure (6,754,034) in column 6 is the total number of years lived after attaining the age of 3 days by the 98,418 reaching that exact age. Similarly, the figure 91,198 in column 5 for white males in the year of life 43-44 is the total number of years lived between their 43d and 44th birthdays by the 91,406 (column 3) who reached the 43d birthday out of the original cohort of 100,000, and the corresponding figure (2,657,169) in column 6 is the total

number of years lived after attaining age 43 by the 91,406 reaching that age.

This number of years divided by the number of persons (2,657,169 divided by 91,406) gives 29.07 years as the average remaining lifetime at age 43. A similar division of 6,754,034 by 98,418 gives 68.63 years as the average remaining lifetime at the age of 3 days.

Care must be exercised in drawing conclusions from the figures in column 7. Thus, in observing that the average remaining lifetime of white persons is greater than that of nonwhites, one should not conclude that the oldest ages reached by white persons necessarily exceed those attained by the most long-lived among the non-white. The difference in average length of life results from the fact that a greater proportion of nonwhites die before reaching old age. For example, the proportion surviving to age 65 is far greater among whites than among nonwhites; yet the average length of life remaining at age 65 is nearly the same for both groups.

TABLE 1. LIFE TABLE FOR THE TOTAL POPULATION: UNITED STATES, 1959-61

AGE INTERVAL	PROPORTION DYING	OF 100,000 BORN ALIVE		STATIONARY POPULATION		AVERAGE REMAINING LIFETIME
Period of life between two ages (1)	Proportion of persons alive at beginning of age interval dying during interval (2)	Number living at beginning of age interval (3)	Number dying during age interval (4)	In the age interval (5)	In this and all subsequent age intervals (6)	Average number of years of life remaining at beginning of age interval (7)
$x$ to $x + t$	$t^q_x$	$I_x$	$t^d_x$	$tL_x$	$T_x$	$\bar{e}_x$
